Abstract

We present a systematic and updated overview of a seismotectonic model for the Po Plain (northern Italy). This flat and apparently quiet tectonic domain is in fact rather active as it comprises the shortened foreland and foredeep of both the Southern Alps and the Northern Apennines. Assessing its seismic hazard is crucial due to the concentration of population, industrial activities and critical infrastructures, but it is also complicated because a) the region is geologically very diverse, and b) nearly all potential seismogenic faults are buried beneath a thick blanket of Pliocene-Pleistocene sediments, and hence can be investigated only indirectly.

Identifying and parameterizing the potential seismogenic faults of the Po Plain requires proper consideration of their depth, geometry, kinematics, earthquake potential and location with respect to the two confronting orogens. To this end we subdivided them into four main homogeneous groups. Over the past 15 years we developed new strategies for coping with this diversity, resorting to different data and modeling approaches as required by each individual fault group.

The most significant faults occur beneath the thrust fronts of the Ferrara-Romagna and Emilia arcs, which correspond to the most advanced and buried portions of the Northern Apennines and were the locus of the destructive May 2012 earthquake sequence. The largest known Po Plain earthquake, however, occurred on an elusive reactivated fault cutting the Alpine foreland south of Verona. Significant earthquakes are expected to be generated also by

1 a set of *transverse structures* segmenting the thrust system, and by the deeper ramps of the
2 Apennines thrusts.

1. Introduction

The Po Plain is one of Italy's major geographical features, extending for over 400 km in a roughly east-west direction from the Alps to the Adriatic Sea and corresponding to the drainage basin of the Po River, the country's longest and most important watercourse. Geologically the Po Plain and part of the current Adriatic Sea comprise the foreland of two opposing verging fold-and-thrust belts: the Southern Alps to the north, and the Northern Apennines to the south. Although it is underlain by actively growing orogens in the context of ongoing convergence, the Po Plain is an almost perfectly flat area that may appear tectonically quiet, bounded by two mountain ranges. The morphological borders of the Po Plain correspond with the contact between the Quaternary alluvium cropping out in the plain and the pre-Quaternary rocks exposed along the two mountain fronts.

Despite the appearances, however, the Po Plain is in itself quite active. Several earthquakes hit the plain and both mountain fronts through history (ISIDE WORKING GROUP, 2010; ROVIDA *et al.*, 2011), testifying that the geodynamic processes which led to the convergence between the two orogens are still active. Due to the occurrence of many historical centers combined with an extraordinary concentration of critical facilities and the associated lifelines, the Po Plain certainly represents a major concern for local administrations and civil defence authorities. Despite these circumstances, and probably due to the scattered nature of local seismicity, much of the Po Plain has entered the Italian seismic code only recently, in 2004, and the new provisions have become mandatory even more recently, in 2010. For these reasons even earthquakes in the magnitude range 5 to 6 can be catastrophic, as tragically demonstrated by the 2012 Emilia sequence (M_L 5.9; ISIDE WORKING GROUP, 2010), which caused 26 casualties and severe damage to monumental and industrial buildings.

1 The Italian earthquake record is normally considered complete for M 6+ earthquakes
2 only for the past ca. 700 years (STUCCHI *et al.*, 2004), but major known earthquakes probably
3 recur every 1,000-2,000 years (VALENSISE and PANTOSTI, 2001a; GALLI *et al.*, 2008).
4 Consequently, faults that released their most recent large earthquake before 700 years ago
5 may not appear in the historical record. Identifying all potential seismogenic faults and
6 estimating their potential is fundamental for characterizing input for probabilistic seismic
7 hazard assessment (PSHA); but given the short length of the historical record and the poor
8 surface expression of potential seismogenic sources, we may be surprised by future damaging
9 earthquakes (MULARGIA, 2013), a fact that was tragically illustrated by the 2012 Emilia
10 sequence. The 20 and 29 May earthquakes occurred in an area for which no historical
11 seismicity was reported but where seismogenic sources had been identified through tectonic
12 geomorphology and seismic profiles (DISS 2.0, VALENSISE and PANTOSTI, 2001b; CIUCCI *et*
13 *al.*, 2002). Resorting to the geological record is hence mandatory for outlining all seismogenic
14 sources of a problematic area such as the Po Plain and assessing its potential effectively (e.g.
15 FACCIOLI, 2013).

16 Fault plane solutions of major instrumental earthquakes show that compressional
17 mechanisms are dominant in the Po Plain (PONDRELLI *et al.*, 2006; SCOGNAMIGLIO *et al.*,
18 2012, among others), which agrees with geologic and modern strain (GPS) evidence (e.g.
19 DEVOTI *et al.*, 2011) and with predictions from geodynamic models. Relatively recent active
20 tectonic studies have acknowledged that faulting is dominantly blind and that strain rates are
21 rather low (see VALENSISE and PANTOSTI, 2001b; BURRATO *et al.*, 2003; BASILI *et al.*, 2008;
22 TOSCANI *et al.*, 2009; DISS WORKING GROUP, 2010; MAESANO *et al.*, 2013; MAESANO *et al.*,
23 submitted). However, correlating individual seismogenic sources and associating them with
24 specific historical earthquakes is not straightforward. A number of additional circumstances
25 add to the complications, including 1) the scattered distribution of seismicity; 2) the large

1 sedimentary rates in the Po Plain proper, often larger than tectonic rates; 3) the presence of
2 inherited landscape and lithological discontinuities in the foothills; 4) locally large man-
3 induced vertical ground motions; and 5) widespread anthropogenic modifications of the
4 natural fluvial network (e.g. the construction of levees and of artificial channels).
5
6
7
8

9 Due to all these circumstances, for many years few investigation of active faults in the
10 subsurface of the Po Plain were begun as most field geologists concentrated on the more
11 visible – and hence more scientifically appealing – faults exposed across the Alps and the
12 Apennines. Identifying and characterizing seismogenic sources in the Po Plain requires an
13 integrated approach that combines morphotectonic analyses, seismicity data and subsurface
14 geological data such as commercial seismic lines, wells, in situ stress measurements, etc.
15
16 Anomalous stream morphology has proven to be the landscape feature that is most sensitive
17 to subtle topographic changes caused by underlying active faults in the flattest portions of the
18 Po Plain, and has been a keystone of our approach (BURRATO *et al.*, 2003; BURRATO *et al.*,
19 2012). In the foothill areas where regional uplift dominates, active thrusting is normally
20 identified by differentially uplifted and tilted Quaternary markers, such as river and even
21 coastal terraces (e.g. AMOROSI *et al.*, 1996, 2004; VANNOLI *et al.*, 2004; PICOTTI and
22 PAZZAGLIA, 2008; PONZA *et al.*, 2010; GUNDERSON *et al.*, 2013, 2014).

41 The case of the Po Plain is especially complex, however, also in view of its extreme
42 tectonic diversity, testified by the wide range of hypocentral depths and focal mechanisms
43 displayed by current seismicity. The characteristic flat-and-ramp structure and arcuate shape
44 of most compressional systems worldwide, including those encircling the Po Plain, imply that
45 active thrust and reverse faults occur at different depths and with different strike, thus
46 requiring multiple and flexible geological approaches and a wealth of subsurface data. The
47 presence of inherited faults in the basement rocks of the Po Plain further complicates the

1 matter, as their reactivation under the current compressional regime may result in earthquakes
2 that are difficult to anticipate based on the evolution of the overlying mountain chains.
3

4 We present an updated overview of the seismogenic sources of the Po Plain and of the
5 two adjacent mountain fronts, most of which are listed in the latest version of the DISS
6 Database (Figure 1), focusing specifically on their existence, geometry, kinematics,
7 earthquake potential and complexity. Their characterization in terms of slip rate and
8 seismogenic potential is required for probabilistic seismic hazard analysis but it is beyond our
9 current scopes. For a summary of strain rates across the Po Plain and beyond the reader may
10 refer to PETRICCA *et al.* (2013) and MAESANO *et al.* (submitted).

21 All potential seismogenic sources correspond to blind faults, which are based on
22 scientific inferences and subject to considerable uncertainties, partially compensated by the
23 exceptional density of underground information. We will discuss the reasoning adopted in
24 each single case, the uncertainties and the research directions that may help setting firmer
25 constraints during future investigation efforts (e.g. FACCIONI, 2013).

44 **2.1 Regional tectonic framework**

45

46 The Po Plain is the foreland of two fold-and-thrust belts verging toward one another: the S-
47 verging central Southern Alps to the north, and the N-NE-verging Northern Apennines to the
48 south. The two belts developed due to convergence between the African and European plates
49 beginning in the Cretaceous, and were associated with two oppositely-dipping subduction
50 zones involving both European and African lithosphere (CARMINATI and DOGLIONI, 2012, and
51 references therein). Hence the Po Plain coincides with the foreland of both chains; it also

1 hosts their foredeeps, and for this reason it has undergone steady subsidence and
2 sedimentation over the past 5 Ma (FANTONI and FRANCIOSI, 2010).
3

4 Buried compressional structures comprising the most advanced fronts of the two
5 orogens were extensively explored by seismic reflection lines and deep well logs obtained for
6 oil exploration after the end of World War II. The local Pliocene-Quaternary sedimentary
7 sequence is characterized by uneven thickness, ranging between several thousand meters in
8 the depocenters to a hundred meters over the top of the buried anticlines (BIGI *et al.*, 1992;
9 GHIELMI *et al.*, 2013). Tectonically-induced, short-wavelength variations in the geometry of
10 the sedimentary sequence are superimposed onto a longer-wavelength signal due to the larger
11 subsidence of the Northern Apennines foredeep with respect to that of the Southern Alps. As
12 a result, the thickness of the sedimentary wedge - and similarly the depth and dip of the basal
13 detachment of the thrust wedge - generally increases towards the Northern Apennines
14 mountain front (i.e., southward; MARIOTTI and DOGLIONI, 2000; BIGI *et al.*, 2003). Rapid
15 asymmetric subsidence caused by the tectonic load of the Northern Apennines chain across
16 the whole Po Plain created a large accommodation space, resulting in large sedimentation
17 rates in the complex system of elongate foredeeps (e.g. BARTOLINI *et al.*, 1996; GHIELMI *et*
18 *al.*, 2013). Subsidence takes place at up to 2-3 mm/a (ARCA and BERETTA, 1985; CARMINATI
19 and MARTINELLI, 2002; CUFFARO *et al.*, 2010) and has always been consistently larger than
20 the tectonic uplift rates along the active thrust-related folds, which caused them to drown in
21 the subsurface of the Po Plain.

48 The outer arcs of the Northern Apennines are currently buried below the Pliocene-
49 Quaternary marine and continental deposits infilling the Po Plain basin and are organized in
50 three complex fold systems: the Monferrato Arc, Emilia Arc, and Ferrara-Romagna Arc,
51 respectively from west to east (Figure 2). To the rear of the Emilia and Ferrara-Romagna arcs
52 the sub-emergent Pedeapenninic Thrust Front (BOCCALETTI *et al.*, 1985) lies at the foot of the

1 Northern Apennines. This important morphological and structural feature has been interpreted
2 in recent studies also as the anticline forelimb of a deeper thrust ramp, and hence not as
3 evidence of a shallow thrust (PICOTTI and PAZZAGLIA, 2008). Such interpretation has
4 significant implications as population concentrates in cities and towns that lie near or on the
5 Pedepenninic Thrust Front; hence establishing whether this is the surface evidence of a string
6 of shallow thrust faults or rather of substantially deeper ramps implies significantly different
7 ground shaking expected in future earthquakes. Continuous Quaternary activity is poorly
8 expressed along the mountain front, yet it is witnessed by progressive deformation and tilting
9 of river terraces and of outcropping syntectonic sediments (e.g. BOCCALETTI *et al.*, 1985,
10 2011; PICOTTI and PAZZAGLIA, 2008; WEGMANN and PAZZAGLIA, 2009; PONZA *et al.*, 2010;
11 GUNDERSON *et al.*, 2013, 2014).

26 In contrast, the buried outer thrust fronts of the Southern Alps exhibit simpler
27 geometries that define a single wide arc running from Milano to the Garda Lake (Figure 2).
28 This outer arc is connected to the east to the NNE-trending Giudicarie thrust system
29 (CASTELLARIN and CANTELLI, 2000; MASSIRONI *et al.*, 2006), and is associated with high
30 angle back-thrusts and small topographic highs emerging in the northern Po Plain that were
31 first investigated by Desio (1965) (see also LIVIO *et al.*, 2009). Unlike the Northern
32 Apennines mountain front, the foothills of the western Southern Alps do not comprise a
33 tectonics-controlled mountain front, the only reported exception being a small area north of
34 Milan (MICHETTI *et al.*, 2012).

48 The active Northern Apennines thrust fronts exhibit a rather complex architecture,
49 comprising potential seismogenic sources corresponding to thrust ramps lying at different
50 structural levels. The occurrence of complex thrust geometries is due to the presence of
51 several potential detachment levels in the sedimentary multilayer deformed by the thrust belt.
52 Potential seismogenic sources include also a deep ramp located between about 12 and 22 km

depth, well imaged in the CROP03 seismic reflection profile as a relatively high angle portion of a regional thrust (BARCHI *et al.*, 1998; FINETTI *et al.*, 2001). This thrust has been interpreted: 1) as a major lithospheric structure, cutting the whole crust from the metamorphic basement up to the higher levels (BARCHI *et al.*, 1998; LAVECCHIA *et al.*, 2003, 2004); or 2) as one of the leading elements of the accretionary prism of the Apennine belt (BALLY *et al.*, 1986; DOGLIONI *et al.*, 1994). In the absence of geological evidence for shortening across this deep ramp, seismicity becomes the only available indicator of its activity. In fact, a number of earthquakes that occurred in the region northeast of the Northern Apennines crest at an estimated depth larger than ordinary (i.e. below 15 km) can be tentatively associated with this structure.

GPS studies show that convergence of Africa and Eurasia at the latitude of northern Italy is progressing at 3 to 8 mm/a (e.g. SERPELLONI *et al.*, 2007) and that shortening across the Po basin proceeds at 1-3 mm/a, increasing from west to east (e.g. DEVOTI *et al.*, 2011). Shortening is accomplished by counter-clockwise rotation of the Adriatic promontory, of which the Po basin is the northern termination, with respect to the European plate, with a pole of rotation located in the western Alps (ANDERSON and JACKSON, 1987; WEBER *et al.*, 2010 and references therein). Borehole breakout data show Sh-max axes perpendicular to the trend of the buried thrust fronts, in agreement with evidence from focal mechanisms (HEIDBACH *et al.*, 2008; MONTONE *et al.*, 2012; CARAFA and BARBA, 2013).

2.2. Paleogeographic control on active tectonics

The Cenozoic compressional architecture of both the Alps and the Apennines was strongly influenced by the inherited Mesozoic palaeogeographic setting of its foreland, i.e. the Adriatic plate. This was characterized by carbonate platforms and deep marine basins, separated by

roughly NNE-trending extensional faults developed during the Tethyan rifting of the ancient African passive margin (BOSELLINI and HSU, 1973; BERTOTTI *et al.*, 1993; CHANNELL, 1996; RAVAGLIA *et al.*, 2006; FANTONI and FRANCIOSI, 2010). As a consequence of this inheritance, the lithosphere progressively deformed by the two thrust belts developed through stratigraphic sequences having uneven thickness and variable sedimentary facies (Table 1). Similarly, the basement rocks and the overlying sedimentary successions involved in the construction of the orogenic belts were characterized by strong lateral variations resulting in strong rheological contrasts (CUFFARO *et al.*, 2010).

The variations in the properties of the subducting lithosphere controlled the evolution and the shape of the thrust fronts, that is to say, the development of salients and recesses respectively in front of basins and carbonate highs (MARIOTTI and DOGLIONI, 2000; CUFFARO *et al.*, 2010). In its turn, the linearity of the thrusts is related to the spacing between subsequent fronts, which is controlled by two important geometrical parameters of the orogen development: 1) the dip of the foreland monocline (MARIOTTI and DOGLIONI, 2000; CUFFARO *et al.*, 2010), and 2) the depth of the basal detachment, i.e. of the deepest thrust of the accretionary prism, usually lying at or near the transition between the crystalline basement and the sedimentary cover (BIGI *et al.*, 2003). Along with the occurrence of shallower detachment horizons resulting from the vertical heterogeneities of the sedimentary sequence, these two properties of the subducting lithosphere have had a profound impact on the subsequent development of the thrust fronts on either side of the Po Plain. Table 1 summarizes how the development of the Alps and Apennines thrusts was controlled by the different characteristics of the sedimentary cover scraped off the foreland lithosphere, and hence of the accretionary prisms, and lists the resulting geometrical characteristics of the two thrust belts. In the following we will discuss some implications of this palaeogeographic control on active faulting.

1 The palaeogeographic inheritance may also have controlled 1) the reactivation in the
2 present-day regime of *inherited* faults that bounded the Mesozoic rift system, and 2) the
3 creation of foreland monocline panels characterized by different dip values; we speculate that
4 such panels are separated by transfer zones characterized by strike-slip or transpressional
5 motion and that are usually perpendicular to the thrust fronts, or *transverse* (see Fig. 4 in
6 CUFFARO *et al.*, 2010; Figure 2). Both types of faults, *inherited* and *transverse*, lie below the
7 basal detachment of the accretionary prisms, being rooted in the lithosphere of the subducting
8 foreland plate. In particular, we expect to find the *transverse* faults only below the Apennines
9 prism, because the initial momentum for their development and kinematics is induced by
10 changes in the dip of the foreland monocline that are seen only beneath the Apennines
11 (MARIOTTI and DOGLIONI, 2000). Although the true geodynamic motivations definitely
12 require further investigation, it is worth nothing that many of the transverse structures that cut
13 across the Apennines (see section on “Transverse structures”) are geographically coincident
14 with the zones where changes in the dip of the monocline are more pronounced. On this basis
15 we propose a genetic relationship between them and the changes in dip of the foreland
16 monocline.

17 Another class of structures rooted in the subducting Adriatic lithosphere includes a set
18 of high-angle normal faults that have been recently discussed in works dealing with the
19 reconstruction of the deep structural setting of the Po Plain (ROGLEDI, 2010). These faults
20 trend at a high angle with respect to the boundaries of the palaeogeographic domains (i.e. E-
21 W to NW-SE); they have been mapped only in the "undeformed" portion of the Po Plain, i.e.
22 beyond the outer fronts of the Alps and Apennines, but have been seen to extend below the
23 Ferrara-Romagna Arc, possibly controlling its geometrical development (TOSCANI *et al.*,
24 2013; BONINI *et al.*, 2014). More specifically, TOSCANI *et al.* (2013) used analogue modeling
25 to show that the location of the thrust ramps associated with the main anticlines has been

controlled by the presence of steps produced by such high-angle faults in the basement morphology. These faults are seen to trend sub-parallel to the inferred direction of the hinge of the foreland monocline, and may hence be optimally oriented for being reactivated due to the bending moment induced by the progressive increase of the monocline dip.

2.3. Seismicity and earthquake budgets

Any investigation of the seismicity of the Po Plain must carefully take into account that in the past both its natural and human landscapes were very different from today. Currently the Po Plain is one of the most densely inhabited and cultivated areas of Italy: however it once was covered by large wooded patches and marshlands, particularly south of the Po river. The reconstruction of the historical seismicity of the Po Plain is a complex task as it implies knowledge of the distribution of settlements and roads of the time. Few large earthquakes are known, the 1117 *Veronese* event being the only one with an inferred $M > 6.5$. Table 2 lists the main parameters of the largest historical earthquakes known to have occurred in the study region (MELONI *et al.*, 1988; BOSCHI and GUIDOBONI, 2003; GUIDOBONI *et al.*, 2007; ROVIDA *et al.*, 2011). In the following sections we will describe these events individually: each one is keyed to a code (IDx) and is tentatively assigned to a seismogenic source (Table 2).

Historical and instrumental catalogues (Tables 2 and 3; CASTELLO *et al.*, 2006; ISIDE WORKING GROUP, 2010) show that the seismicity of the Po Plain concentrates along the foothills and the buried thrust fronts of the Northern Apennines and Southern Alps (Figure 3), with a few notable exceptions including the 3 January 1117 earthquake (M_w 6.7, *Veronese*; ID 6). In general the Northern Apennines fronts exhibit more historical earthquakes than the Southern Alps fronts. Seismicity is not evenly distributed, however, but increases from west to east, i.e. from the Monferrato to the Ferrara-Romagna Arc.

As recalled earlier, the present-day activity of the two mountain fronts is characterized by compressional focal mechanisms (<http://www.bo.ingv.it/RCMT/searchRCMT.html>; PONDRELLI *et al.*, 2006), in full agreement with tectonic evidence. The 20 and 29 May 2012 Emilia earthquakes (M_L 5.9 and 5.8, respectively; Table 3), the largest earthquakes ever recorded instrumentally in the region, were caused by purely reverse slip with Sh -max axes perpendicular to the buried thrust faults of the western Ferrara-Romagna Arc (e.g. SCOGNAMIGLIO *et al.*, 2012, among others). The 2012 sequence was highly complex as a total of seven $M5+$ earthquakes occurred during the long aftershock sequence (about 2,500 events), activating a ~50 km-long stretch of this buried outer front. Most of the earthquakes occurred between 1 and 12 km depth, above the basal detachment of the outer thrust fronts.

Earthquake sequences characterized by multiple, similarly large mainshocks are rather common over the whole Italian territory (see Table 4 and Figure 4). In addition to stress transfer among adjacent faults, their occurrence is likely related to the country's structural complexity, which causes the active fault systems to be broken up by numerous transverse structures; on the one hand these effectively limit the fault length that may rupture in a single large earthquake, but on the other hand they make the triggering of adjacent faults more likely. The complex sequences of the Po Plain and surrounding areas are shown in Tables 2 and 3 and are highlighted in Figure 3b.

The Po Plain is also the locus of relatively deep earthquakes, conventionally assumed to coincide with all events located below 15 km depth. They occur below the basal detachment of the Northern Apennines and Southern Alps and therefore are not directly related to thrust tectonics. Two deep earthquakes that were felt over a large portion of northern and central Italy occurred in 2012 near Reggio nell'Emilia (25 January, M_L 5.0, depth 29.0 km; ID 41) and near Parma (27 January, M_L 5.2, depth 72.4 km; ID 63). Some historical earthquakes have affected large portions of the Po Plain and of the surrounding

1 ranges, causing widespread damage and suggesting that deeper events are a common
2 occurrence in the region. For example, the effects of the 13 January 1909, M_w 5.5, *Bassa*
3 *Padana* earthquake (ID 16) are documented by 800 intensity points spread over an area of
4 about 180.000 km², and by 297 points with intensity V (N_v) or larger (see panel b in Figure
5 5). As first suggested by MELONI and MOLIN (1987), the 1909 event may have occurred at a
6 relatively large depth, up to 40 km according to FACCIOLI (2013). These deep earthquakes
7 may attain a significant magnitude, as shown by the 1909 event; in fact their true magnitude is
8 likely to be substantially larger than the 5.5 estimate obtained from intensity data with
9 automatic routine procedures, normally calibrated using upper crustal events. Therefore, the
10 occurrence of such deep earthquakes cannot be ignored in developing a seismotectonic model
11 of the Po Plain. Reasonably reliable depth data, however, are available only for earthquakes of
12 the past thirty years. For older events we did not attempt a formal determination of the
13 hypocentral depth, but we used the ratio of epicentral intensity and felt area and some expert
14 judgment simply to separate deeper from shallower events. All earthquakes having M 5.3+
15 were thus carefully inspected and their intensity patterns compared (Figure 5). Tables 2 and 3
16 list all earthquakes having an estimated depth below 15 km (highlighted in Figure 3b).

Based on the data presented in Tables 2 and 3 we analyzed the seismic release of the
Po Plain and of the Apennines foothills in terms of shallow vs. deep earthquakes, with
reference to the historical and to the most recent seismicity (Table 5). Even considering the
limited completeness of the historical record, the total observed moment release (3.31×10^{26}
dyne cm, equivalent to a single M_w 7.0 earthquake) is rather small, especially if compared
with the size of the investigated area (nearly 40,000 km²). This result must be considered also
in light of the known limited *earthquake efficiency* of the Po Plain as a whole (BARBA *et al.*,
2010). Shallow earthquakes dominate the global seismic release, but deep events release more
moment over the instrumental time window, in spite of the large contribution to shallow

moment release supplied by the 2012 Emilia sequence. This suggests (a) that deep historical events are under-represented, or (b) that their magnitude is systematically underestimated, or a combination of these two end-members.

3. Seismogenic sources of the Po Plain

3.1. Generalities

In this section we identify and characterize the main seismogenic sources that affect the Po Plain, i.e. those believed to be capable of producing $M \geq 5.5$ earthquakes (VALENSISE and PANTOSTI, 2001b; BASILI *et al.*, 2008).

The approach employed for compiling the DISS database is based on substantial geological and geophysical evidence. The strategy is based on two categories of sources: the *Individual Seismogenic Sources* (ISS; stored in the database with a unique code beginning with ITIS followed by a three digit number), and the *Composite Seismogenic Sources* (CSS; stored in the database with a unique code beginning with ITCS followed by a three digit number). The first category includes individual fault segments that may be responsible for specific historical or instrumental earthquakes, whereas the second category represents fault systems that may include one or more ISSs. Detailed descriptions of the DISS sources and the multi-step procedure to identify their parameters can be found in BASILI *et al.* (2008), BASILI *et al.* (2009), BURRATO *et al.* (2008), VANNOLI *et al.* (2012), KASTELIC *et al.* (2013) and on the database website (<http://diss.rm.ingv.it/diss/UserManual.html>).

Following the rationale of the DISS database, our work aims to represent an *updated* and hopefully *complete* portrait of the seismogenic sources recognized in the Po Plain. The *completeness* of the data is normally assessed with reference to the observed seismicity,

making sure that no significant historical earthquake is left unassigned to a mapped source. The sparseness of the historical record, however, makes this assessment rather difficult and potentially misleading. In fact, the geological moment release that can be calculated for the Po Plain sources outpaces the observed historical moment release, suggesting that either the historical earthquake record is incomplete, or that their *seismic coupling*, or *earthquake efficiency*, is rather low (e.g. BARBA *et al.*, 2010). This crucial aspect of the characterization of Po Plain sources is out of the scopes of this paper but will be the object of a future research effort.

As stated earlier, the seismogenic sources of the Po Plain originate from diverse geodynamic processes, occur at various depth, exhibit different kinematics, and as such they may induce very different ground shaking. For all of these reasons we subdivided them into four main groups (Figure 6):

Group #1) shallow thrusts of the Alps and Apennines fold-and-thrust belts, which include fault systems occurring along the Alps and Apennines piedmont and more external fronts extending further into and beneath the Po Plain;

Group #2) deep ramps of the Apennines fold-and-thrust belts occurring beneath the Northern Apennines, northeast of the main drainage divide;

Group #3) inherited faults of the foreland, which includes older structures such as Mesozoic normal faults reactivated under the current compressional tectonic regime;

Group #4) transverse structures, faults that are roughly perpendicular to the main structural grain of the Northern Apennines thrust belt.

Sources of Group #1 pose a significant hazard as they occur at shallow depth and near the more densely populated areas (e.g. Figures 5 and 6 in ZONNO *et al.*, 2012). As such they are also somehow easier to identify despite their blind nature. Conversely, sources of Group

#2 and #4 are usually responsible for moderate ground shaking over large areas, which partially compensates the difficulties involved in locating them precisely. Finally, sources of Group #3 are perhaps the most dangerous as they are the most elusive, and hence their earthquake potential is most uncertain. As discussed in the following, the largest known earthquake of the Po Plain (3 January 1117, M_w 6.7) is believed to belong to this group. Although Groups #1 and #2 exhibit similar kinematics, we decided to keep them separate as their impact on ground shaking is very different due to their location and depth.

In this section we describe each *CSS* and *ISS* of the Po Plain included in the current version of the DISS database (version 3.2.0), from north to south and from west to east. For the study area DISS lists 21 *CSSs* and 13 *ISSs* (Figure 7). The sources in the DISS database belong to Groups #1, #2, and #3. Sources of Group #4 are still being evaluated for possible inclusion at a later time.

Following is an example of the data used and the reasoning adopted for characterizing an Individual Source, namely the source of the 4 April 1781, Romagna earthquake (M_w 5.9; ID 23, ITIS093). This upper crustal blind source (Group #1) is associated with gentle warping of the Apennines foothills and drainage anomalies. Its three-dimensional geometry was defined according to the following observations:

- the location was chosen by matching the larger faults that exists in the subsurface with the earthquake macroseismic pattern;
- the strike was based on the local trend of the Pedeapenninic Thrust Front;
- the dips was set at 35° to the south, as suggested by subsurface data;
- the rake was assumed to be pure thrusting, based on geodynamic considerations constrained by mesostructures affecting recent deposits of the area;

- the length was evaluated based on subsurface data and on the extent of landscape modifications induced by fault activity, and was constrained by scaling relationships with the magnitude of the 4 April 1781 earthquake;
- the down-dip width was assessed based on subsurface data and constrained using the magnitude of the 1781 earthquake;
- finally, the minimum and maximum depth were constrained by analysis of subsurface data.

Although the Po Plain has been the object of intense investigations since the inception of the DISS database, some potential sources of damaging earthquakes still need to be fully characterized. The existence of most of these new sources has been highlighted by the occurrence of earthquakes that, due to their location and hypocentral depth, cannot be associated with the Alps and Apennines thrust systems, and hence belong to Groups #3 and #4 (see above). Some of these sources have been included in v. 3.2.0 of the DISS database, to be published in 2014, whereas others will be included in future releases.

3.2. Shallow sources of the Alps and Apennines fold-and-thrust belts (Group #1)

The Seismogenic Sources belonging to this group correspond to the shallow outer thrusts of the S-verging Central Southern Alps and of the N-verging Northern Apennines fronts that exist in the subsurface of the northern and southern Po Plain, respectively. Active compression in the Po Plain generates moderate seismicity along complex thrust systems and intervening strike-slip faults, an interpretation supported by available seismological, GPS and stress field data. The occurrence of salients and recesses along strike of the main thrust fronts creates boundaries to the dynamic earthquake propagation, causing segmentation of the compressional fault systems and, therefore, of the relevant CSSs.

The following description is based on a comprehensive instrumental catalogue (ISIDE: ISIDE WORKING GROUP, 2010) and on historical catalogues (BOSCHI *et al.*, 2000; GUIDOBONI *et al.*, 2007; ROVIDA *et al.*, 2011). For an in-depth description of each source and a complete list of references the reader may refer to the DISS website (<http://diss.rm.ingv.it/diss/>). All historical and instrumental earthquakes mentioned in the text are listed in Tables 2 and 3 and are highlighted in Figure 3 through their identifier (ID).

Geodetic (D'AGOSTINO *et al.*, 2008), seismological (ISIDE WORKING GROUP, 2010; ROVIDA *et al.*, 2011) and tectonic (MAESANO *et al.*, submitted) evidence suggests that convergence rates decrease from east to west across the whole Po Plain. Slow tectonic activity characterizes the Monferrato Arc (Figure 2; e.g. MICHETTI *et al.*, 2012 and references therein), in the westernmost portion of the Po Plain, and seismicity nearly disappears west of the longitude of Milan. For these reasons the thrusts of the western end of the Southern Alps and of the Northern Apennines that fall in an area roughly corresponding with the administrative region of Piedmont have not yet been included in the DISS database. The only notable exceptions are the sources of the 2 and 16 April 1808, Val Pellice earthquakes (M_w 5.7, 5.6), located off the western end of the Monferrato Arc at the Alps foothills. Nevertheless, we believe that an in-depth analysis of the structures of the Monferrato Arc is mandatory as they show distinct evidence of mild recent activity and may hence generate very infrequent earthquakes.

3.2.1. Shallow thrusts of the central Southern Alps margin

The southernmost compressional fault system of the Alps is a buried S-verging external arc that is clearly imaged by subsurface data between Milano and the Garda Lake (Figure 7; PIERI and GROPPi, 1981; CASSANO *et al.*, 1986; FANTONI and FRANCIOSI, 2010). The ITCS002

follows faithfully this poorly expressed blind thrust fault system. This portion of the Po Plain exhibits a lower seismic release compared to areas to the east and north-east (STUCCHI *et al.*, 2008), yet we believe that structures belonging to the ITCS002 are responsible for the 12 May 1802 *Valle dell'Oglio* earthquake and possibly for the 26 November 1396 *Monza* earthquake (ID 2 and 1, respectively). The ITCS002 includes the *ISS* responsible for the 1802 earthquake (ITIS104: see Figure 7 and Tables 6 and 7) whose location and geometry are based on geomorphological evidence supplied by BURRATO *et al.* (2003), on oil industry data (e.g. PIERI and GROPPi, 1981; CASSANO *et al.*, 1986; FANTONI and FRANCIOSI, 2010) and on macroseismic data, that uniquely constrain the location of the thrust responsible for the 1802 event (ALBINI and ROVIDA, 2010). Due to lack of suitable geological and macroseismic constraints, no *ISS* was derived for the 1396 event.

The S-verging front is accompanied by an active N-verging high-angle back-thrust located southwest of the Garda Lake (Figure 7; ITCS072). This source is associated with some of the small topographic highs first investigated and interpreted as culminations of anticlines related to buried compressional faults by DESIO (1965), later investigated by LIVIO *et al.* (2009) using shallow seismic reflection profiles. Both the frontal thrust (ITCS002) and its associated backthrust (ITCS072) are blind and their propagation toward the surface is expressed by secondary folds and fault planes (MICHETTI *et al.*, 2012). The frontal thrust and the backthrust exhibit a cumulative displacement of 1,200 and 5,700 m, respectively. The cumulative slip rate dropped from 3.45 mm/a in the interval 1.6-1.2 Ma to 2.75 mm/a between 1.2 and 0.9 Ma and 0.47 mm/a from 0.9 Ma to Present, with consistently larger deformation being accommodated on the backthrust with respect to the frontal thrust during the most recent period (LIVIO *et al.*, 2009). Based on its macroseismic signature the 25 December 1222 *Basso Bresciano* earthquake (M_w 5.8; ID 4) may have been generated by either of these

1 structures, both large enough to generate an event of that size, but the data not allow to
2 discriminate between these two scenarios.
3

4 The buried outer arc of the Southern Alps is connected to the east with the NNE-
5 trending Giudicarie System (Figures 2 and 7), commonly interpreted as a regional transfer
6 zone between the Central and Eastern Southern Alps (e.g. CASTELLARIN and CANTELLI,
7 2000). The Giudicarie System developed along the border between Lombardian basin, to the
8 west, and the Trento platform, to the east. The ITCS073 straddles the region east of the Garda
9 Lake and corresponds to a SE-verging more external arc assumed to be an active ramp of the
10 Giudicarie System. The role and geometry of this source is based on regional geological data
11 (e.g. CASTALDINI and PANIZZA, 1991). Historical and instrumental catalogues show scattered
12 intermediate-size earthquakes across this region.

26 The ITCS048 is a S- to SE-verging internal thrust ramp of the Giudicarie System. The
27 30 October 1901 Salò earthquake occurred in this area (M_w 5.7; ID 3; PESSINA *et al.*, 2013),
28 followed about a century later and virtually in the same area by a further damaging thrust
29 faulting earthquake on 24 November 2004 (M_L 5.2, *Lago di Garda*; ID 39). The 1901 *Salò*
30 earthquake has been associated with a segment of the ITCS048. The *Salò* Individual Source
31 (ITIS069) is a 7 km-long, 231°-striking, NW-dipping blind thrust fault comprising a deeper
32 ramp of the Giudicarie System. The depth of the ITIS069 was assigned based on felt reports
33 of the 1901 earthquake. The 2004 earthquake occurred few kilometers north of the *Salò*
34 source and was caused by slip on a portion of the ITCS048 source (PESSINA *et al.*, 2006). The
35 focal solution of the 2004 event further constrained and confirmed the parameters of the
36 existing 1901 earthquake seismogenic source (ITIS069).

65

seismicity along strike of this thrust front. The role and geometry of this source are based on regional subsurface geological and geophysical data (e.g. CASTALDINI and PANIZZA, 1991).

3.2.2. *Shallow thrusts of the Northern Apennines margin*

The northernmost compressional fault system of the Northern Apennines is arranged in a series of N-verging thrust fronts: from west to east, they are the outermost Emilia Arc, the Ferrara-Romagna Arc and, to the south, the Pedeapenninic Thrust Front (Figure 7).

Emilia Arc

The ITCS018 is the westernmost source of the Emilia Arc and lies south of Pavia, beneath the region extending from the Po River to the Northern Apennines foothills. Historical and instrumental catalogues show little seismicity in this area, with the notable exception of the 9 October 1828 earthquake (M_w 5.8; ID 7), that hit the *Valle dello Staffora* area close to the southwestern boundary of the source.

The ITCS044 source straddles the region between Pavia and Cremona. This area is characterized by minor seismicity with the exception of the 28 July 1276 (M_w 5.1) earthquake. The San Colombano active fold, one of the few anticlines emerging in the Po Plain (TOSCANI *et al.*, 2006), is the only surface expression of this source. Based on modeling of the geometry of the fold and of the associated growth strata, and adjusting the measured tectonic deformation with back-stripping of the differential compaction of the sediment, MAESANO *et al.* (submitted) calculated for this source an average slip rate of 0.48-0.54 mm/a over the past 1.81 Ma.

The ITCS009 source runs in a NW-SE direction from Cremona to Reggio nell'Emilia. A number of damaging earthquakes hit this area over historical times, the most important of

which occurred on 11 June 1438 (M_w 5.6, *Parmense*; ID 9), 11 September 1831 (M_w 5.5, *Reggiano*; ID 12), and 15 July 1971 (M_w 5.7, *Parmense*; ID 10). Based on their peculiar intensity patterns, the 13 March 1832 (M_w 5.5, *Reggiano*; ID 11) and 9 November 1983 (M_L 4.8, *Parmense*; ID 62; Figure 5c) earthquakes appear to be deeper than other events, and for this reason they may be tentatively interpreted as belonging to Group #4 (see below). The 1831 and 1832 earthquakes are close both in space and time, a phenomenon that is rather common for the Italian seismicity as shown also by the 2012 Emilia sequence (see Figure 4 and Tables 2, 3 and 4). The average Pleistocene slip rate calculated for this source falls in the range 0.16-0.53 mm/a (MAESANO *et al.*, submitted).

Ferrara-Romagna Arc

The ITCS049 is the westernmost source straddling the Ferrara-Romagna Arc. It extends to the NE of the city of Reggio nell'Emilia and follows the lateral ramp of the arc. This source accounts for a number of intermediate-size yet damaging earthquakes: 10 February 1547 (M_w 5.1, *Reggio Emilia*), 20 June 1671 (M_w 5.2, *Rubiera*), 12 February 1806 (M_w 5.2, *Novellara*), 25 Dec 1810 (M_w 5.3, *Novellara*), 24 April 1987 (M_L 4.6; ID 44), 15 October 1996 (M_w 5.4; ID 42), and 18 June 2000 (M_w 4.5, *Parmense*; ID 43). Based on the intensity pattern the 2 May 1987 earthquake (M_w 4.5; *Reggiano*; ID 45) may have been generated by a deep source, and for this reason it may be assigned to Group #4 (see below). The average post-middle Pleistocene slip rate calculated for this source falls in the range 0.04-0.16 mm/a (MAESANO *et al.*, submitted).

The ITCS050 follows the most external thrust front of the Northern Apennines. Infrequent activity characterizes this portion of the plain with the only exception of the 22 February 1346 (M_w 4.9, *Ferrara*) and 17 November 1570 (M_w 5.5, *Ferrara*; ID 13; Figure 5a) earthquakes. The 1346 event is crucial for the understanding of the earthquake potential of

1 this region as it may have been located close to the events of the 2012 Emilia sequence;
2 unfortunately its macroseismic signature is insufficient to derive any firm conclusions
3 concerning its focal parameters, starting with the magnitude, and further investigations are
4 needed.
5
6
7
8
9

10 The most significant earthquake recorded in instrumental times occurred on 17 July
11 2011 (M_L 4.8; ID 59; Figure 3; MASSA *et al.*, 2012); it was located along the outermost front
12 and had a reverse focal mechanism. In contrast with its low seismic activity, this area may
13 hold a significant seismogenic potential, as suggested by subsurface geological and
14 geophysical data (PIERI and GROPPi, 1981; BOCCALETTI and MARTELLI, 2004; MAESANO *et*
15 *al.*, submitted) and by evidence of active surface deformation (BURRATO *et al.*, 2003). The
16 1570 *Ferrara* earthquake was associated with an individual thrust of this arc and identified as
17 ITIS090 (DISS Working Group, 2010). Its location and geometry are based on subsurface
18 geological and geophysical information constrained by geomorphological observation of the
19 occurrence of drainage anomalies on top of the buried structure.

31
32
33

34 The ITCS103 extends across the lower Secchia River and Panaro River valleys.
35 Seismicity is sparse, but recent studies of historical sources suggest that a moderate-size
36 earthquake, probably overlooked by previous workers, occurred on 6 April 1639 (CASTELLI *et*
37 *al.*, 2012). The 2012 Emilia sequence, which began with the 20 May 2012 earthquake
38 (ITIS134 source), activated a 10 km-long portion of the ITCS103 (Figure 7; Table 8).
39 Subsurface data (App_Orien-1 seismic line, available from
40 <http://unmig.sviluppoeconomico.gov.it/videpi/>) show well developed buried anticlines (Figure
41 8), and the coseismic deformation of the ground-surface caused by the 20 May 2012
42 earthquake (BIGNAMI *et al.*, 2012; PEZZO *et al.*, 2013, TIZZANI *et al.*, 2013) is consistent with
43 the characteristics of this seismogenic source.

The ITCS051 source encompasses the region across the lower Secchia River and Reno River valleys. CASTELLI *et al.* (2012) found historical evidence of moderate-size earthquakes that occurred in the area on 15 December 1761 and 11 May 1778. Subsurface data (e.g., CASSANO *et al.*, 1986) show a number of well developed buried folds, the largest being the Mirandola anticline. BURRATO *et al.* (2003) proposed that a segment of the blind thrust imaged by subsurface data could be the source of infrequent M_w 5.5 or larger earthquakes in this area. The ITIS107 *Mirandola* source was identified on the basis of tectonic geomorphology observations and considerations, stressing the relationships between peculiar drainage anomalies and a major buried active fault. Between Sorbara and San Prospero the Secchia and Panaro rivers are drawn toward the earthquake epicentral area, whereas between San Felice sul Panaro and Mirandola they are pushed away from it. The existence of the ITIS107 source explains well the drainage i) being attracted towards a locally subsiding area, and ii) being diverted away from an uplifted area. As the ITIS107 *Mirandola* was not associated with any historical earthquake, its assigned M_w 6.2 was derived only from the geologically constraints on the source size. This potential seismogenic source was included in the version of DISS database presented in 2000 (v. 1.0) and published in 2001 (v. 2.0, VALENSISE and PANTOSTI, 2001b). The 29 May 2012 earthquake and its associated sequence were caused by the activation of a portion of ITCS051. Notably, the 29 May mainshock may have been caused by the ITIS107 itself, and the ITCS051 source has been identified in DISS as the source responsible for the uplift of the Mirandola anticline. The coseismic deformation of the ground-surface caused by the 29 May 2012 earthquake and measured by SAR interferometry (see BIGNAMI *et al.*, 2012, among others; Table 8) is consistent with predictions based on modeling of the characteristics of this seismogenic source. The source responsible for the 29 May 2012 event is described in detail in BURRATO *et al.* (2012). The average middle Pleistocene slip rate calculated for this source falls in the range 0.50-1.04

mm/a (MAESANO *et al.*, submitted); this figure is specifically based on observations carried out along sections across the buried Mirandola anticline.

The ITCS012 source extends across the lower Reno River valley and strikes E-W to NW-SE. A number of moderate-size to damaging events have affected the area, including the 19 March 1624 (M_w 5.5, *Argenta*; ID 14) and 30 December 1967 (M_w 5.2, *Bassa Padana*) earthquakes. The 1624 earthquake is assumed to have been caused by the ITIS141 source. The ITCS012 corresponds to the most advanced of the Romagna thrust fronts and marks their termination to the east. The average middle Pleistocene slip rate calculated for this source falls in the range 0.49-0.55 mm/a (MAESANO *et al.*, submitted).

The ITCS109 and ITCS011 extend over the portion of the Po Plain located east of Bologna. These fault systems correspond to NE-verging inner arcs located north of the Romagna foothills. Local seismicity is sparse and moderate in size, with the exceptions of the 10 July 1591 (M_w 5.2, *Forlì*) and 11 April 1688 earthquakes (M_w 5.8, *Romagna*; ID 22). Subsurface data (PIERI AND GROPPi, 1981; CASSANO *et al.*, 1986; FANTONI and FRANCIOSI, 2010) and evidence from a number of investigators point to fast active surface deformation resulting from the tectonic activity of the buried anticlines at the rear of the Ferrara-Romagna Arc. The average middle Pleistocene slip rate calculated for the ITCS011 falls in the range 0.15-0.33 mm/a (MAESANO *et al.*, submitted). A segment of the ITCS109 (ITIS100) has been hypothesized as the source of the 11 April 1688, *Romagna* earthquake. The location and geometry of this source were based on a comparison between the 1688 damage pattern and the location of major thrusts of the Ferrara-Romagna Arc in the subsurface, whereas its size was scaled to the M_w 5.8 obtained from intensity data.

Pedeapenninic Thrust Front

The ITCS045, ITCS046, ITCS047, and ITCS001 sources run along the Pedepenninic Thrust Front. They are NE-verging thrusts and folds generating the geomorphology of the Emilia-Romagna foothills (e.g. PONZA *et al.*, 2010). Their present-day activity and seismogenic potential are suggested by subsurface geophysical data (PIERI and GROPPi, 1981; CASSANO *et al.*, 1986; BRUNO *et al.*, 2011), evidence of drainage anomalies (AMOROSI *et al.*, 1996), structural data (CASTELLARIN *et al.*, 1985), morphotectonic analyses (PICOTTI and PAZZAGLIA, 2008; PONZA *et al.*, 2010; GUNDERSON *et al.*, 2013), and evidence from past seismicity.

In our interpretation, the ITCS045 source marks the western end of the active Northern Apennines mountain front and has been the locus of few moderate-size earthquakes. The ITCS046 source extends across the region south of the city of Reggio nell'Emilia. Moderate-size and damaging earthquakes are numerous but sparse all across the area. Key earthquakes have occurred on 5 June 1501 (M_w 6.0, *Appennino Modenese*; ID 18), 9 December 1818 (M_w 5.2, *Langhirano*), and 4 March 1898 (M_w 5.4, *Valle del Parma*; ID 17). A moderate-size earthquake took place in 91 B.C. (M_w 5.7, *Modena-Reggio Emilia*) just north of this area, but its location is inevitably very uncertain (GUIDOBONI *et al.*, 2007).

The ITCS047 extends across the upper Reno River valley, near the city of Bologna. The region is the locus of both moderate-size and damaging earthquake, mostly concentrated in its central and western portions. Key earthquakes occurred on 25 July 1365 (M_w 5.4, *Bologna*; ID 21), 20 July 1399 (M_w 5.1, *Modenese*), 3 January 1505 (M_w 5.6, *Bolognese*; ID 20), and 20 April 1929 (M_w 5.3, *Bolognese*; ID 19). BOSCHI and GUIDOBONI (2003) listed a number of moderate-size earthquakes that occurred near Bologna and its surroundings, including the 4 May 1433 (I=VI MCS), 6 February 1455 (I=VIII MCS), and 20 December 1455 (I=VI-VII MCS) events. The 1929 and 1505 earthquakes have been associated with two portions of ITCS047 (ITIS103 and ITIS091, respectively). The ITIS103 and the ITIS091 sources are consistent with evidence of recent activity of the Pedepenninic Thrust Front

southwest of Bologna, which includes triangular facets, the presence of a growing anticline and a fault scarp across Holocene alluvial fans. The rivers flowing southeast of Bologna are characterized by erosional behavior and uplifted terraces (e.g. PICOTTI and PAZZAGLIA, 2008). The location of the ITIS103 source is consistent with the largest damage reported following the 1929 earthquake. In the same area GUIDOBONI *et al.* (2007) reported landslides, surface fractures and enhanced gas discharge in nearby gas and mud volcanoes. The location of the source is constrained to the east by the proximity with the ITIS091 source, assumed to be the causative fault of the 3 January 1505 earthquake located between Zola Predosa and Bologna. Also this source was set in agreement with the largest reported damage, and also for this area GUIDOBONI *et al.* (2007) reported diffuse landslides and surface fractures, while PRESTININZI and ROMEO (2000) reported liquefaction at Zola Predosa. The location of the ITIS091 source is constrained to the east by the location of another M_w 5.1 earthquake on 20 January 1505 (BOSCHI and GUIDOBONI, 2003), and to the west by the location of the 20 April 1929 earthquake.

The ITCS001 source encompasses the region to the west of the upper Savio River valley. The region exhibits a concentration of both moderate-size and damaging earthquakes, including the 4 August 1383 (M_w 5.4, *Forlì*; ID 25), 3 July 1428 (M_w 5.5, *Predappio*; ID 27), 11 August 1483 (M_w 5.7, *Romagna meridionale*; ID 26), 4 April 1781 (M_w 5.9, *Romagna*; ID 23), 17 July 1781 (M_w 5.6, *Romagna*; ID 24), 21 September 1813 (M_w 5.3, *Romagna centrale*), 30 October 1870 (M_w 5.6, *Romagna*; ID 28), and 19 February 1911 (M_w 5.2, *Romagna meridionale*) events. The two 1781 earthquakes comprise an additional case of “twin events” discussed earlier on (see Figure 4 and Table 4). An earthquake swarm caused by slip on WNW-ESE striking blind thrusts between 7 and 14 km depth occurred in the area in 2000 (mainshock on 10 May 2000, M_L 4.5; ID 67). Based on observations of this sequence CALDERONI *et al.* (2009) provided new insight on the role of fluids involved in the

1 seismogenic process. A segment of the ITCS001 is believed to be responsible for the 4 April
2 1781 earthquake (ITIS093). Our source model is consistent with the location of the largest
3 damage, and the macroseismic pattern is suggestive of a shallow fault (see the “Generalities”
4 section for further details on this source). In contrast, PICOTTI *et al.* (2009) hypothesized that
5 the 1781 earthquake was produced by the *Riolo Terme* normal fault. This fault belongs to a
6 set of normal faults occurring along the foothills of the Northern Apennines, showing
7 evidence of recent activity and interpreted to develop along the outer shell of a large growing
8 anticline as a consequence of a local inversion of the stress field (PICOTTI *et al.*, 2009). This
9 interpretation, however, does not agree with the damage distribution of the 4 April 1781
10 earthquake as it leaves most of the largest intensity data points in the footwall of the fault, in
11 contrast with the common observation that the strongest shaking due to a dip-slip fault is
12 experienced in the hangingwall. The seismogenic potential of the normal faults investigated
13 by PICOTTI *et al.* (2009) is also at odds with their secondary nature, as they most likely formed
14 as a consequence of surface warping driven by a blind thrust. This further stresses the
15 hypothesis that the main seismogenic source is the blind thrust itself.

41 **3.3. Deep ramps of the Northern Apennines (Group #2)**

42 The ITCS027 source is the most internal compressional Composite Source of the Northern
43 Apennines. As anticipated in the “Regional tectonic framework” section, this source
44 corresponds with a deep thrust that has been interpreted either as a major lithospheric
45 structure cutting the whole crust from the metamorphic basement up to the higher levels, or as
46 one of the leading elements of the accretionary prism of the Apennines belt. In the latter case
47 the earthquakes would generate at the interface where the sedimentary cover is delaminated
48 from the metamorphic basement. The main differences between the two end-members in the

65

interpretation of the structural style of this region concern the position of the basal *decollement* level of the thrusting and the presence or absence of secondary *decollement* levels. Some investigators (e.g. BALLY *et al.*, 1986; DOGLIONI *et al.*, 1994) indicate the bottom of the Triassic evaporites as the basal *decollement* level, and propose that the Palaeogene-Neogene evolution of the belt has been characterized by thin-skinned tectonics. Others (e.g. BARCHI *et al.*, 1998; FINETTI *et al.*, 2001; LAVECCHIA *et al.*, 2003) contend that also the upper portion of the magnetic basement was involved in thrusting, and support a thick-skinned structural style. In general most workers (e.g. BARCHI *et al.*, 1998; COWARD *et al.*, 1999) agree on the presence of two main *decollement* levels inside the accretionary prism; the lower coincides with the bottom of the Triassic evaporites, on which the major thrust ramps originate, whereas the shallower coincides with the Marne a Fucoidi or Scaglia Cinerea formation, the level marking the detachment of minor thrusts sheets. As a result, also the deformation style is characterized by two main structural levels: 1) a lower level, consisting of deep and broad anticlines produced by deep thrust faults detaching on the Triassic evaporites and causing deformation of the overlying Mesozoic-Palaeogene carbonate succession evaporates; and 2) an upper level, made up of small and tight anticlines lying in the axial zones of the major anticlines and developed in the Neogene foredeep sediments. These latter structures exhibit a more complex structural pattern with respect to the deeper ones.

We believe that the northwesternmost portion of the ITCS027 source is responsible for the 25 June 1869 (M_w 5.4, *Media Valle del Reno*; ID 30), 14 September 2003 (M_w 5.3, *Appennino bolognese*; ID 66) and 23 December 2008 (M_L 4.8 and 5.4, *Parmense*; ID 64 and 65) earthquakes; the two most recent events exhibit a depth around 20 km and reverse focal mechanisms. The ITCS027 contains two *ISSs*, the ITIS135 and ITIS058 (Figure 7). The ITIS135 is a 4.9 km-long, N98°-striking, S-dipping blind thrust fault that is held responsible for the 23 December 2008, M_w 5.4 earthquake. Its strike, dip and rake were chosen based on

the earthquake focal solution (<http://www.bo.ingv.it/RCMT/searchRCMT.html>; PONDRELLI *et al.*, 2011). The mainshock occurred at 24 km depth and most of the aftershocks occurred below 20 km depth (ISIDE WORKING GROUP, 2010). As a result, the earthquake was felt over a large area (INGV, <http://www.haisentitoilterremoto.it/repository/2205007630/index.html>; ERCOLANI *et al.*, 2009).

The ITIS058 source is a 4 km-long, N94°-striking, S-dipping blind thrust fault thought to be the source of the 14 September 2003, M_w 5.3, earthquake. Similarly to the previous event, this deeper earthquake was felt over a large area but caused no damage, and its focal parameters were chosen based on its RCMT focal solution. The mainshock was located at 20 km depth; the aftershocks occurred between 15 and 22 km depth and showed a sharp NE-SW alignment. Almost all of the aftershocks were located E of the mainshock. Based on the depth distribution of the aftershocks PICCININI *et al.* (2006) suggested that the mainshock occurred on a NW-dipping back-thrust of the Northern Apennines. Conversely, we propose that the mainshock occurred on a SE-dipping plane, but then triggered an aftershock sequence along a deep, subvertical fault probably corresponding with the Prato-Sillaro Line (PSL in Figure 9; see the following section on “Transverse structures” for further details).

3.4. Inherited faults of the foreland (Group #3)

Inherited faults belonging to the Mesozoic rift system and reactivated in the present-day tectonic regime represent the potential sources of perhaps the largest earthquakes that occur beneath the Po Plain, such as the 3 January 1117, M_w 6.7 *Veronese* earthquake (ID 6; Table 2; Figure 3) located to the south of the Lessini mountains. Updated macroseismic intensity data for this event clearly show that the area of greatest damage lies in the Adige plain south of Verona (GUIDOBONI *et al.*, 2005). Perhaps because of the widespread effects and the fact that

1 the epicentral area has always been considered an undeformed portion of the foreland, all
2 previous investigators located the 1117 event 30-50 km away from the macroseismic
3 epicenter; either along exposed fault systems, such as the Veneto thrust front (GALADINI *et*
4 *al.*, 2005), or along known buried faults, such as the thrust underlying the Piadena anticline
5 (GALLI, 2005).
6
7
8
9

10
11 Our hypothesis for the source of the 1117 earthquake is included in DISS as ITIS140
12 (ITCS076; Figure 7). Its identification and parameters are based on the analysis and joint
13 interpretation of subsurface data and morphometric indicators of the drainage pattern in the
14 portion of the Adige plain where the largest damage was reported. In the framework of an
15 investigation of drainage patterns in the entire Po Plain, BURRATO *et al.* (2003) found that the
16 Mincio and Adige river courses exhibit an anomalous behavior. A subsequent study identified
17 drainage and topographic anomalies also along minor rivers of the area, all compatible with
18 the existence of a buried reverse fault which would induce vertical relative ground motions in
19 the region lying between the mid-course of the Adige and Mincio rivers. The best fitting
20 reverse fault derived from modeling of these anomalies was seen to match a buried structure
21 recognized in seismic exploration lines, a former extensional fault that is suitably oriented
22 (ENE-WSW) for being reactivated under the current stress field. For an in-depth description
23 of this source and its references the reader may refer to
24 <http://diss.rm.ingv.it/dissHTML/ITCS076INF.html>.

45

46 Owing to their location and inferred hypocentral depth, infrequent events beneath the
47 Po Plain may be associated with the reactivation of inherited faults. Among these, the 15 May
48 1951, M_w 5.4 *Lodigiano* earthquake (ID 8) occurred in a poorly investigated region between
49 the more advanced fronts of the Northern Apennines and those of the Southern Alps, north of
50 the Emilia Arc (Figure 9a). Its location is made less certain by its unusual intensity pattern,
51 which appears rather spread out thus suggesting a deeper source (MELONI *et al.*, 1988).

1 Nevertheless, the 1951 event falls outside the two compressional systems and far from any of
2 the transverse structures discussed in the next section (Figure 3). For this reason we suggest it
3 may have been generated by one of the inherited faults of the foreland, even if its true
4 seismogenic source has not been identified yet. The location of this earthquake was already
5 reported as unusual by CALOI *et al.* (1956), who remarked that it falls in a totally aseismic
6 region. Owing to the presence of several productive gas fields in the epicentral area, they
7 concluded that the event could be seen as an induced earthquake, which would explain its
8 unusual location. Based on its presumably large depth, however, and to the ongoing
9 compression between the Emilia Arc and the Southern Alps, we rather interpret the 1951
10 earthquake as a natural event generated by one of the inherited faults that exist in the
11 metamorphic basement (ROGLEDI, 2010; Figure 9a).

26 Two other candidate earthquakes for having been generated by inherited fault systems
27 are the 22 October 1796, M_w 5.6 *Emilia orientale* and the 13 January 1909, M_w 5.5 *Bassa*
28 *Padana* “deep” earthquakes (ID 15 and 16, respectively). These events are located close to
29 each other within the Ferrara-Romagna Arc. As discussed in the following section, they
30 occurred beneath the Po Plain at a hypothesized depth that causes them to fall below the basal
31 detachment of the thrust wedge. As discussed below, their causative faults are still under
32 investigation and may belong to Group #4.

3.5. Transverse structures (Group #4)

51 The transverse structures are expressed as lineaments oriented mainly northeast-southwest in
52 the Northern Apennines thrust belt, hence roughly perpendicular to the chain, and northwest-
53 southeast across the Southern Alps. They were hypothesized as early as the ‘50s based on
54 geomorphological observations and on evident lithological and facies discontinuities in the

1 regional geological texture (e.g. SIGNORINI, 1953; BOCCALETTI *et al.*, 1977; FAZZINI and
2 GELMINI, 1982 for the Apennines; CASTELLARIN and VAI, 1986; CASTELLARIN *et al.*, 1998,
3 for the Alps). Although their nature and kinematics are still largely unknown, they seem to
4 subdivide the Northern Apennines and Southern Alps thrust fronts into 30-50 km-long
5 sections (e.g. CASTELLARIN *et al.*, 1985). In the first public release of the DISS database (v.
6 2.0, VALENSISE and PANTOSTI, 2001b) they were compiled, georeferenced and plotted along
7 with known seismogenic sources and major earthquakes, suggesting 1) that they play a
8 passive role in controlling the current distribution of seismic release, but also 2) that they may
9 themselves host significant earthquakes. Unfortunately there is little evidence for the exact
10 geometry and the activity of these lineaments, both at the surface and in the subsurface, and
11 even their role in the geodynamic framework of the Northern Apennines and Southern Alps is
12 still the matter of debate (e.g. SORGI *et al.* 1998; ELTER *et al.*, 2012).

13 Most of the CSSs discussed in this paper terminate where the most significant of such
14 transverse structures bound palaeogeographic domains, effectively acting as boundaries to
15 earthquake propagation. The CSSs of the Southern Alps are bounded to the east by the Schio-
16 Vicenza Line (Figure 7), a NW-SE, 120-km long, subvertical strike-slip fault (e.g.
17 PELLEGRINI, 1988; CASTALDINI and PANIZZA, 1991; VIGANÒ *et al.*, 2008). The Schio-Vicenza
18 Line does not appear to have generated earthquakes larger than magnitude 5.5, but significant
19 earthquakes are expected along the neighboring CSSs of the Eastern Southern Alps, shown in
20 blue in Figure 1 (see GALADINI *et al.*, 2005, and BURRATO *et al.*, 2008 for an overview).

21 We interpreted the transverse structures as the brittle response of the upper lithosphere
22 to the lateral changes in the geometry of the subducting slab as reflected in the dip of the
23 foreland monocline (MARIOTTI and DOGLIONI, 2000). This interpretation is based on the
24 observation that 1) the thrust belts show undulations controlled by inherited Mesozoic horsts
25 and grabens (see section on “Palaeogeographic control on active tectonics”), with recesses

1 occurring around horsts and salients developing in grabens (Table 1), and that 2) the
2 terminations of these undulations match the transverse structures and are reflected in the
3 shape of the CSSs, resulting in first-order segmentation of the compressional fault systems.
4
5

6
7 The deeper earthquakes play a central, albeit poorly understood, role in the assessment
8 of the seismogenic potential of these transverse structures. Over the past few decades a
9 significant amount of moment has been released in relatively deep earthquakes generated by
10 unknown sources. Figure 9a shows the lineaments (i.e. transverse structures) reported in the
11 literature, and the instrumental and historical earthquakes deeper than 15 km (see Tables 2
12 and 3). The focal mechanisms of these deep earthquakes are both reverse and strike-slip. In
13 detail:

- 26 • the source of the 13 September 1989, M_L 4.7 earthquake (ID 40), having a depth of 40 km
27 and a strike-slip focal mechanism, falls below the Schio-Vicenza Line and is hence
28 assigned to it;
29
30
31
32
- 33 • the majority of deep instrumental and historical earthquakes (ID 41, 45, 11, 62, 29, and
34 63) fall in a relatively small area of the Apennines and Pedepennines. The 13 March
35 1832, M_w 5.5 (ID 11) and the 17 September 1873, M_w 5.4 (ID 29) earthquakes exhibit the
36 characteristic signature of deep earthquakes (Figure 5). The 2 May 1987, M_L 4.5 (ID 45)
37 and the 9 November 1983, M_L 4.8 (ID 62; Figure 5c) events are both reported at a depth
38 around 25 km and exhibit strike-slip and transpressional focal mechanisms, respectively.
39 The 25 January 2012, M_L 5.0 (ID 41) and the 27 January 2012, M_L 5.2 (ID 63)
40 earthquakes exhibit a depth of 29 and 72 km with transtensional and reverse kinematics,
41 respectively. The location of all these events corresponds to the location of significant
42 lateral changes in the foreland monocline. The monocline plunges beneath the Apennines
43 thrust belts and accretionary wedges with a dip that varies laterally between 14°, 8° and
44

23°. This area is a crucial crossroad as it controls the forward propagation of the shallow thrusts, ultimately causing a significant northward shift of the Po River near Guastalla. Furthermore this area of deformation falls at the northern end of a major transverse structure, namely the Enza Line (EL in Figure 9), a strike-slip fault inferred from stratigraphic and structural data displaying dip-slip kinematics in Middle-Late Pliocene-Pleistocene (CASTELLARIN *et al.*, 1985);

- we propose that the source of 3 October 2012, M_L 4.5 earthquake (ID 61), having a depth around 30 km and a strike-slip focal mechanism, marks a less visible transverse structure located in between the Upper Val Trebbia and Stirone-Ongina Lines (CASTELLARIN *et al.*, 1985);
- the 25 June 1869, M_w 5.4 earthquake (ID 30) is a deep event that occurred near the junction of the Apennines deep ramps and the Viareggio-Val di Lima-Bologna transverse structure (VVL in Figure 9). As such, it might belong equally well to Group #2 or #4;
- the 14 September 2003, M_w 5.3 earthquake (ID 66) already described in Group #2 makes an interesting case. With a depth of about 20 km and a reverse focal mechanism its mainshock is likely to have been generated by one of the deep ramps; but the subsequent aftershock sequence delineated likely a deep, subvertical fault probably corresponding with the Prato-Sillaro Line (PSL in Figure 9). This transverse structure is inferred from remote sensing, surface geology and structural data (BOCCALETTI *et al.*, 1985; CASTELLARIN *et al.*, 1985);
- the 22 October 1796, M_w 5.6 (ID 15) and 13 January 1909, M_w 5.5 (ID 16; Figure 5b) earthquakes exhibit the characteristic signature of the deep earthquakes, and occurred at approximately the same location of the southeastern Po Plain (see section on “Seismicity and earthquake budgets”). These two events are therefore below the thrusts of the Ferrara-Romagna arc. In principle they may have been caused by as yet unknown inherited

structures of the Group #3. Their locations, however, fall near a strong lateral variation of the dip of the foreland monocline, possibly marking the extension of the Prato-Sillaro Line (PSL in Figure 9) beneath the Po Plain deposits. To the south, west of the Mugello basin, the same lineament appears to interrupt the continuity of the Etrurian Fault System, a major extensional system straddling the crest of the Northern Apennines (Figure 9a). When placed in a palaeogeographic perspective, the Prato-Sillaro Line appears much as the mirror image to of the Enza Line, although less obvious. We conclude that the 1796 and 1909 earthquakes may have been generated by the northeastern extension of the Prato-Sillaro Line, and should hence belong to Group #4;

- the 5 April 2009, M_L 4.6 earthquake (ID 68), occurred with a transpressional focal mechanism below the shallow Pedepenninic Thrust Front, but at a depth of about 25 km. Based on its location, this event could have been generated by the Montone Line (ML in Figure 9a), therefore belonging to Group #4;
- finally, the 6 June 2012, M_L 4.5 earthquake (ID 60) occurred in the Adriatic Sea, just a few kilometers offshore, at the eastern end of the Ferrara-Romagna arc. Its 26 km depth and the dominantly strike-slip mechanism suggest it may be evidence for a sort of “rebound” of the eastern end of the arc only a few days after the strong shocks of 20 and 29 May 2012.

In summary, a number of sizable historical and instrumental earthquakes of the Northern Apennines seem to follow well defined trends that correspond with the main mapped transverse lineaments. This circumstance is further stressed by the seismic release pattern delineated by the 2009-2013 sequences (Figure 9b). Indeed these mostly shallow sequences occurred far from the inherited faults described above (belonging to Group #3), but seem to delineate well the pattern of the transverse structures. These structures also play an

important passive role in the propagation of ground shaking caused by significant deeper earthquakes (e.g. see the 25 January 2012 earthquake: <http://mappe.haisentitoilterremoto.it/2221246460/index.html>, or the 27 January 2012 earthquake: <http://mappe.haisentitoilterremoto.it/2221279330/mcs.jpg>, both of which propagated efficiently southeastward only up to the Prato-Sillaro Line). Similarly, the aftershocks of the 2012 *Emilia* sequence terminated against the Secchia Line (SL in Figure 9b), which played an obvious passive role.

4. Discussion and conclusions

4.1. Identifying seismogenic sources in the Po Plain

The correct identification of seismogenic sources in the Po Plain is a crucial and extremely complex task that requires unconventional data and innovative approaches and methodologies. As most of the seismogenic faults are blind and cannot be detected by standard field mapping, the vast majority of the relevant input must be derived from subsurface data, drainage and sedimentary patterns, and seismicity.

Despite these unfavorable circumstances, the investigation of the local seismotectonic setting is somewhat easier than in other parts of the Italian peninsula. The Po Plain has undergone steady compression and shortening from the Upper Pliocene to Present, generating a relatively monotonous series of thrust faulting systems that are progressively younger as one moves from west to east and from the inner to the outer portions of the two confronting orogens, the Alps and the Apennines. In marked contrast, the inner portions of the Apennines have witnessed a recent and drastic change in the dominant stress field and the onset of significant regional uplift. The combination of these two circumstances makes field mapping

1 especially difficult and potentially misleading, as the limited cumulated effects of the present-
2 day extensional tectonics are masked by the occurrence of faults generated under previous
3 regimes and rejuvenated by the ongoing uplift (VALENSISE and PANTOSTI, 2001a).
4
5

6
7 Current slip rates are relatively low on faults of the Po Plain, implying more infrequent
8 earthquakes and hence a lower seismic hazard. The analysis of cumulative strain over
9 different time intervals, however, shows that at least in the southern portion of the Po Plain
10 deformation used to be faster but has steadily slowed down in recent geological times
11 (MAESANO *et al.*, submitted).
12
13
14
15
16
17

18
19 The correct estimation of slip rates requires proper considerations of the effects of
20 differential compaction (SCROCCA *et al.*, 2007; MAESANO *et al.*, 2013; MAESANO *et al.*,
21 submitted). The cumulative shortening of the two confronting orogens has created significant
22 relief in the subsurface, where carbonate ridges nearly reaching the topographic surface are
23 juxtaposed to deep troughs filled by as many as 8,000 m of Pliocene-Pleistocene sediments.
24 These deposits are naturally bound to reduce their volume; the expected volume reduction,
25 however, is proportional to the thickness of the unconsolidated sedimentary layers, which
26 varies greatly from place to place. As a result, the compaction will be differential, i.e. it will
27 be more pronounced in the deep troughs than on top of the anticlines (e.g. MAESANO *et al.*,
28 2013). The ensuing differential volume loss may simulate the outcomes of tectonic activity
29 even over long time periods after activity has ceased. In other words, tectonic activity
30 associated with crustal shortening promotes the creation of uplifted areas, where
31 sedimentation is limited or absent, and lowlands, that act as sediment traps; but differential
32 compaction itself induces relative thickness changes of the sedimentary layers, simulating the
33 geometry of growth strata and causing a trade-off between the outcomes of genuine tectonic
34 activity and standard sedimentary effects. All in all, differential compaction may lead to a
35 gross overestimation of the tectonic rates, in the milder cases, or to mistaking a dead for an

1 active fault, in the most severe instances. Assessing the role of differential compaction is
2 hence a crucial step in the assessment of the earthquake potential of faults buried by a thick
3
4 blanket of unconsolidated sediments
5
6

7 Accurate seismic hazard assessment in the Po Plain is important due to the large
8
9 number of industries and critical infrastructures and to the concentration of over 10 million
10
11 people, about 20% of the country's population. And even though Po Plain earthquakes are
12
13 generally quite moderate compared to those located in peninsular Italy, anticipating where,
14
15 how frequently and how strongly that may strike takes on a special significance and requires
16
17 special care. As in many other *problematic* areas worldwide, no individual dataset alone may
18
19 allow to identify all seismogenic sources unambiguously, and resorting to a blend of diverse
20
21 observations becomes mandatory. Due to the limited geological strain rates and to the
22
23 sparseness of seismicity, any conclusion must be carefully constrained by regional-scale
24
25 geodynamic models and evidence for ongoing deformation (GPS). The seismotectonic model
26
27 presented in this paper is indeed the result of such blending, and is also a scheme that will be
28
29 easy to test as more data become available.

41 **4.2. Observed and expected seismicity**

42
43
44

45 The Po Plain is the locus of moderate-size (normally $< M\ 6.0$) and infrequent earthquakes, at
46
47 least compared to peninsular Italy, and probably for this reason its seismic hazard has long
48
49 been underrecognized. Earthquake codes have acknowledged the local earthquake potential
50
51 only since 2004, and it has taken six more years for the new provisions to be fully enforced.
52
53
54
55
56 This has resulted in inadequate earthquake protection which largely explains the human loss
57

1 and material caused by the May 2012 Emilia earthquakes (M_L 5.9 and 5.8), when 27 people
2 died in collapsed factory buildings (STUCCHI *et al.*, 2012).
3

4 We subdivided the damaging Po Plain earthquakes into shallow and deep, depending
5 on whether they occur above or below 15 km depth (Figure 3; Tables 2, 3). Shallow events
6 are more damaging and sometimes catastrophic, whereas deep events usually do not cause
7 extreme damage but are strongly felt over large areas (Figure 5). In summary the Po Plain is
8 expected to experience (see Figure 5 and Table 5):
9

- 10 • shallow damaging earthquakes, such as the 17 November 1570 *Ferrara* and the 20-29
11 May 2012 *Emilia* events, which are responsible for 84-96% of the total moment release
12 (depending on the time frame considered);
13
- 14 • deep earthquakes, such as the 13 January 1909 *Bassa Padana* and the 9 November 1983
15 *Parmense* events, which are responsible for 16-4% of the total moment release (depending
16 on the time frame considered);
17
- 18 • sequences with multiple mainshocks, such as the 1504-1505 *Bolognese*, the 1570 *Ferrara*,
19 the 1781 *Faenza*, the 1916 *Rimini* and the 2012 *Emilia* events; in fact, the majority of
20 crustal earthquakes, both historical and instrumental, exhibit this characteristic behavior
21 (Table 4 and Figure 4); and
22
- 23 • infrequent destructive earthquakes, such as the 3 January 1117, M_w 6.7 *Veronese* event,
24 that are difficult to anticipate as they are generated by the least known category of
25 seismogenic sources of the Po Plain (*inherited faults*, Group #3).

49
50

51 Shallow earthquakes occur following a relatively regular pattern along major
52 identified buried thrusts, with a concentration on the external front of the Ferrara-Romagna
53 Arc and on the Pedepenninic Thrust Front (Figure 3). In contrast, deep earthquakes are
54 concentrated in relatively small areas, possibly coincident with the transverse structures
55
56
57
58
59
60
61
62
63
64
65

(Figures 3b and 9a). All in all, the Northern Apennines structures (Emilia Arc, Ferrara-Romagna Arc and Pedeapenninic Thrust Front) exhibit a larger seismogenic release compared to the Southern Alps (Southern Alps Outer Arc plus Southern Alps Mountain Front), both in historical times and instrumental. More specifically (Figures 3, 7):

- the earthquake potential of the main fronts of the Northern Apennines increases from west (Monferrato Arc, Emilia Arc) to east (Ferrara-Romagna Arc);
- the Pedeapenninic Thrust Front, that lies close and beneath the main urban areas of Emilia-Romagna, has released significantly in historical times but has been almost totally quiescent in the past few decades;
- the *deep ramps* host a small fraction of the total earthquake potential;
- multiple sequences occur preferentially on shallow thrusts, and specifically on those belonging to the Emilia and Ferrara-Romagna Arcs.

Finally, Po Plain seismogenic sources exhibit a large variability in terms of maximum magnitude, ranging from 5.5 to 6.7 (Figure 10). Sources expected to generate the strongest earthquakes include that responsible for 1117 earthquake (ITIS140, ITCS076) and the *deep ramps* (ITCS027). Sources of the Ferrara-Romagna Arc, of the Pedeapenninic Thrust Front and the thrusts and backthrust of the outer arc of the Southern Alps are known to have generated earthquakes up to M_w 6.1. Finally, sources of the Southern Alps Mountain Front, of the Giudicarie System and of the Emilia Arc have not exceeded M_w 5.7 historically.

4.3. Summary and open issues

We described a large set of seismogenic sources encompassing the Po Plain. The vast majority of the sources exhibit a minimum and maximum faulting depth of 1-5 km and 7-10

1 km, respectively, reflecting the characteristic geometries and depths of the Alps and
2 Apennines accretionary wedges. Exceptions are the *deep ramps* (ITCS027), where
3 earthquakes are assumed to take place at a depth of 12-22 km, and the *transverse structures*,
4 that appear to generate seismicity over a wide depth range.
5
6
7

8
9 Due to obvious geological reasons, the accuracy of our seismotectonic model
10 decreases rapidly as faulting depth increases. If it may be reassuring to learn that most of the
11 moment is released by shallower and hence easier to identify sources, we must keep in mind
12 that they also cause the strongest ground shaking. In contrast, future earthquakes are likely to
13 be spawned by deep and largely unexplored seismogenic sources, but we also know that the
14 associated ground shaking will be milder. The investigation of these deep sources is a priority
15 for future research efforts. These will necessarily include an improved consideration of the
16 role exerted on thrust development by the palaeogeography of the Alpine margin, a
17 clarification of the role of the *transverse structures* cross-cutting the Northern Apennines, and
18 a reassessment of the seismotectonic evidence supplied by seismicity.

30
31
32
33

34 Perhaps the main obstacle towards a better understanding and more accurate
35 assessment of the earthquake potential of the Po Plain, however, is the question of the limited
36 *earthquake efficiency* or *seismic coupling* of the local seismogenic sources. BARBA *et al.*
37 (2010) have shown that the seismic moment released by the compressional earthquake
38 sources encircling the Po Plain is less than 25% of the moment estimated from geological
39 observations and geodynamic modeling. This begs the question: is low efficiency a permanent
40 characteristic of the Po Plain, or perhaps of all similar thrust faulting systems worldwide?
41 Does *low efficiency* imply that the same faults behave seismically and aseismically at the
42 same time, or does it mean that many faults slip aseismically without ever generating
43 earthquakes while a few only slip coseismically? There may well be a deficit in historical

65

1 moment release, but how accurately do we know the historical earthquake record? Can we
2 rule out the occurrence of rare large earthquakes that would rebalance the earthquake budget?
3

4 Instrumental monitoring of the Po Plain has provided reliable earthquake locations and
5 focal mechanisms over the past 30 years. In contrast, the historical seismicity record is likely
6 to be incomplete for at least two reasons. The first and principal reason has to do with the
7 environmental characteristics of large portions of the Po Plain. Unbeknown to many, this
8 industrialized and heavily urbanized part of Italy was once covered by large forests and
9 marshlands, and hence sparsely populated. Before the construction of large modern levees,
10 some of which were completed as late as the end of the XVII century, many Po Plain rivers
11 wandered across the plain driven by the distribution of topographic highs and lows. The
12 second reason is that much of the seismic moment may have been released in deep
13 earthquakes, but since these cause only mild shaking many of such events may have gone
14 undetected through history and until relatively recent times.
15

18
19
20
21
22
23
24
25
26
27
28
29
30

31 As a result, the pre-instrumental earthquake record may be locally incomplete,
32 particularly in the marshy areas of the southern Po Plain between the Ferrara-Romagna Arc
33 and the Pedepenninic Thrust Front. Much of the available information refers to earthquakes
34 recorded at the cultural and economic centers, such as Ferrara and Mirandola, normally
35 located in *dry spots* on top of buried anticlines, making it difficult to separate small local from
36 larger and more distant events. This implies that the effective *completeness* of the Po Plain
37 earthquake record may be as short as a few centuries, even where tectonic deformation is
38 fastest such as in the central-southern Po Plain, thus inducing and explaining the known fast
39 landscape changes.

Figure Captions

Figure 1: Composite Seismogenic Sources of the DISS database. Sources of the Po Plain are shown in red and described in this work; sources of northeastern Italy and western Slovenia are shown in blue and described in BURRATO *et al.*, 2008; sources of the Adriatic Domain are shown in green and described in KASTELIC *et al.*, 2013; extensional sources of the Central Apennines are shown in yellow and described in VANNOLI *et al.*, 2012; other sources in orange.

Figure 2: Structural sketch of the Po Plain. Key - black lines: main structural elements (BIGI *et al.*, 1992); white lines: inherited faults (ROGLEDI, 2010); dashed lines: transverse structures (e.g. CASTELLARIN *et al.*, 1985); grey horizontal shading: Trento Platform (CUFFARO *et al.*, 2010). SAMF: Southern Alps Mountain Front; SAOA: Southern Alps Outer Arc; GS: Southern Alpine Giudicarie System; SVL: Schio-Vicenza Line; NAOA: Northern Apennines Outer Arcs; PTF: Pedepenninic Thrust Front; MA: Monferrato Arc; EA: Emilia Arc; FRA: Ferrara-Romagna Arc.

Figure 3: Historical and instrumental earthquakes from the CPTI11 Catalogue (<http://emidius.mi.ingv.it/CPTI11/>), Bollettino Sismico Italiano (<http://bollettinosismico.rm.ingv.it/>) and ISIDe (<http://iside.rm.ingv.it/>). Historical earthquakes have $M \geq 5.3$ and are shown with squares. Instrumental earthquakes have $M \geq 4.5$ and are shown with circles ($M 4.5-4.9$) or stars ($M \geq 5.0$). All earthquakes are keyed to Tables 2 and 3 through their ID. The IDs of instrumental earthquakes are shown in italic.

a) Available focal mechanisms (PONDRELLI *et al.*, 2006; TDMT database: <http://cnt.rm.ingv.it/tdmt.html>; see Table 3 for focal parameters.

b) Earthquake locations: *deep* historical and instrumental earthquakes are shown in bold; multiple events are shown with a grey pattern.

Figure 4: Largest Italian earthquake sequences ($M_w \geq 5.7$) of the past 50 years (1962-2012: data from CPTI11; see Table 4). A multiple sequence includes at least two earthquakes with comparable magnitudes. Multiple sequences are shown with white lettering on black background. Inset shows frequency of multiple events for different kinematics.

Figure 5: Maps of macroseismic intensity V and higher for the 1570 (a), 1909 (b) and 1983 (c) earthquakes (LOCATI *et al.*, 2011) and for the 20 May 2012 (d) earthquake (TERTULLIANI *et al.*, 2012b). The earthquake epicenters are shown with white stars. N_V is the number of the data points with intensity V or larger. Notice the large felt area of the 1909 and 1983 earthquakes, suggesting that the depth of these events is larger than the depth of the 1570 and 2012 events.

Figure 6: Sketch showing the four groups of seismogenic sources identified in this work. Group #1: Shallow thrusts of the Northern Apennines, including the sub-emergent Pedepenninic Thrust Front; Group #2: Deep ramps of the Apennines thrusts; Group #3: Inherited faults cutting the foreland; Group #4: Transverse structures (or *lineaments*), interpreted as the response of the upper lithosphere to the variation of the dip of the regional monocline. EA: Emilia Arc; FRA: Ferrara-Romagna Arc; PTF: Pedepenninic Thrust Front.

Figure 7: Composite and Individual Sources of the Po Plain, respectively shown as red ribbons and black rectangles. Reaches of anomalous drainage (from BURRATO *et al.*, 2003) are marked in white. SAMF: Southern Alps Mountain Front; SAOA: Southern Alps Outer Arc; GS: Southern Alpine Giudicarie System; SVL: Schio-Vicenza Line; PTF: Pedepenninic Thrust Front; EA: Emilia Arc; FRA: Ferrara-Romagna Arc.

Figure 8: a) Sketch of the seismogenic sources of the Northern Apennines thrust fronts in the epicentral area of the 2012 seismic sequence, and b) simplified geological section. Contour lines of observed surface deformation from InSAR data (with maximum uplift value in cm) are shown in white (BIGNAMI *et al.*, 2012). The isolines of the dip of the foreland monocline are shown in grey (MARIOTTI and DOGLIONI, 2000, reinterpreted): numbers indicate the dip of the Apennines monocline along the three sections (MARIOTTI and DOGLIONI, 2000). The dashed line shows the Secchia Line (SL; northern segment: CASTALDINI *et al.*, 1979; southern segment: CASTELLARIN *et al.*, 1985).

Figure 9: Seismotectonic sketch of the Po Plain and principal paleogeographic elements. The isolines contour the dip of the foreland monocline (MARIOTTI and DOGLIONI, 2000, reworked). Grey ribbons: CSSs (DISS WORKING GROUP). White (in 9a)/grey (in 9b) solid lines: inherited faults from ROGLEDI (2010). Grey shaded area: Trento Platform from

CUFFARO *et al.* (2010). Grey dashed lines: transverse structures; SVL, Schio-Vicenza Line; VTL, Val Trebbia Line; SOL, Stirone-Ongina Line; TEL, Taro-Enza Line; EL, Enza Line; SL, Secchia Line; VVL, Viareggio-Val di Lima-Bologna Line; PSL, Prato-Sillaro Line; ML, Montone Line; AVML, Arbia-Val Marecchia Line (from CASTELLARIN *et al.*, 1985).

a) Map showing deep earthquakes with $M > 4.5$. Squares: historical (Table 2). Circles and stars: instrumental (Table 3) with $M > 4.5$ and depth > 15 km (circles, $M 4.5-4.9$; stars $M \geq 5.0$). EFS: Etrurian Fault System.

b) Map of earthquake sequences ($M \geq 2.0$) that occurred in the interval 1 January 2009-31 December 2013 (ISIDE WORKING GROUP, 2010).

Figure 10: Maximum expected magnitude estimated for all the Composite Seismogenic Sources from the database DISS discussed in this work.

Characteristics	Basins (Lombardian/Belluno)	Platforms (Trento/Friuli)	Control on thrust geometry
Thickness of sedimentary sequence	thicker	thinner	---
Depositional facies	deep marine	shallow water carbonates	<i>number of detachment levels</i>
Multiple detachment horizons	yes	no	<i>presence of different wavelength structures</i>
Dip of foreland monocline	steep	shallow	<i>spacing among thrust fronts</i>
Depth of basal detachment	deep	shallow	<i>spacing among thrust fronts</i>
Spacing among thrust fronts	wide	small	<i>development of salients and recesses</i>
Trend/linearity of thrust front	salients	recesses	---

Table 1: Summary of the characteristics of palaeogeographic domains in the central Po Plain, and control exerted on thrust geometry (observations mostly from CUFFARO *et al.*, 2010, reinterpreted).

ID	Date	Locality	Intensity	M _w	Multiple	Deep	Description/Notes	Source(s)	Group	Tectonic structure
6	3 Jan 1117	Veronese	IX	6.7	N/A	N/A	GUIDOBONI and COMASTRI (2005) reported an independent earthquake (5 intensity points, I=VII-VIII) occurring on the same day, at the same hour, but 150 km to the south, in the territory of Pisa.	ITIS140; ITCS076	#3	N/A
4	25 Dec 1222	Basso Bresciano	IX	5.8	N/A	N	The source of this earthquake could be the either the thrust or the backthrust.	ITCS002 or ITCS072 (see “Notes”)	#1	SAOA
33	30 Apr 1279	Rocca San Casciano	VII-VIII	5.6	N/A	N/A	Only 5 intensity datapoints. The CFTI catalogue reports 1 May 1279, M _w 5.9, I=VIII (at 2:00 AM). The CPTI does not report an event on 1 May but rather two events on 30 April, one near Rocca San Casciano (I =VII-VIII), one near Camerino (I=X).	ITCS027	#2	DR
21	25 Jul 1365	Bologna	VII-VIII	5.4	N/A	N	Only one intensity datapoint available. Some sources refer to a 7 April shock, other more reliable sources to a 25 July shock. Two earthquakes struck Ferrara on 4 March (M _w 4.8) and Verona on 21 September (M _w 4.5).	ITCS047	#1	PTF
25	4 Aug 1383	Forlì	VII-VIII	5.4	N/A	N	Only one intensity datapoint available. Preceded by M _w 4.1 shock on 24 July 1383 near Parma.	ITCS001	#1	PTF
1	26 Nov 1396	Monza	VII-VIII	5.4	N/A	N/A	Only one intensity datapoint available.	ITCS002	#1	SAOA
27	3 Jul 1428	Predappio	VIII	5.5	N/A	N	---	ITCS001	#1	PTF
9	11 Jun 1438	Parmense	VIII	5.6	N/A	N	---	ITCS009	#1	EA
26	11 Aug 1483	Romagna meridionale	VIII-IX	5.7	N/A	N	BARATTA (1901) reports a shock near Ferrara on 11 March 1483 and one near Cervia in 1484.	ITCS001	#1	PTF
18	5 Jun 1501	Appennino modenese	IX	6.0	N/A	N	---	ITCS046	#1	PTF
20	3 Jan 1505	Bolognese	VIII	5.6	Y	N	The earthquake sequence started on 31 Dec 1504 (M _w 5.4) and ended 19 May 1505 (BOSCHI and GUIDOBONI, 2003).	ITIS091; ITCS047	#1	PTF
13	17 Nov 1570	Ferrara	VIII	5.5	Y	N	The earthquake sequence started on 17 November 1570, went on with closely spaced aftershocks up to early 1572, and gradually died out until 17 March 1574, when a somewhat stronger shock caused further damage in Finale Emilia	ITIS090; ITCS050	#1	FRA

							(GUIDOBONI <i>et al.</i> , 2007).			
32	-- --- 1600	Palazzuolo	VII-VIII	5.4	N/A	N/A	Only one intensity datapoint available.		N/A	N/A
14	19 Mar 1624	Argenta	VIII-IX	5.5	N/A	N	---	ITIS141; ITCS012	#1	FRA
34	22 Mar 1661	Appennino romagnolo	X	6.1	N/A	N	---		4	AVML
22	11 Apr 1688	Romagna	IX	5.8	N/A	N	“... a large aftershock near Russi on 18 April 1688, a week after the mainshock” (BOSCHI <i>et al.</i> , 1997). Not reported in the CFTI catalogue.	ITIS100; ITCS109	#1	FRA
31	29 Oct 1725	Appennino Tosco-emiliano	VIII	5.4	N/A	N	Located about 10 km to the east of the 14 September 2003, M _w 5.3, Appennino Bolognese earthquake (ID 66).		#4	PSL
23	4 Apr 1781	Romagna	IX-X	5.9	Y	N	---	ITIS093; ITCS001	#1	PTF
24	17 Jul 1781	Romagna	VIII	5.6	Y	N	---	ITCS001	#1	PTF
38	25 Dec 1786	Riminese	VIII	5.6	N/A	N	The Composite and Individual Sources responsible for this earthquake are described in KASTELIC <i>et al.</i> (2013).	ITIS035; ITCS039	#1	N/A
15	22 Oct 1796	Emilia orientale	VII	5.6	N/A	Y	This earthquake falls near the ITCS012, but at a deeper depth. The epicentral area is very close to that of the 1909 earthquake (ID 16).	---	#4	PSL
2	12 May 1802	Valle dell'Oglio	VIII	5.6	N/A	N	---	ITIS104; ITCS002	#1	SAOA
7	9 Oct 1828	Valle Staffora	VIII	5.8	Y	N	---	ITCS018	#1	EA
12	11 Sep 1831	Reggiano	VII-VIII	5.5	Y	N	The 1831 event fall at the junction between the EA and the FRA. Given the complex local seismotectonic pattern, this event may has been caused by two adjacent segments of the EA (ITCS009) or FRA (ITCS049).	ITCS009; ITCS049	#1	EA/ FRA
11	13 Mar 1832	Reggiano	VII-VIII	5.5	Y	Y	The 1832 event is deeper than the ITCS009 and the ITCS049.	---	#4	EL
30	25 Jun 1869	Media Valle del Reno	VII-VIII	5.4	N/A	Y	This is a deep event that occurred near the junction of the Apennines deep ramps and the Viareggio-Val di Lima-Bologna transverse structure. As such, it might be equally well assigned to Group #2 o #4.	---	#2/4	DR/ VVL
28	30 Oct 1870	Romagna	VIII	5.6	N/A	N	---	ITCS001	#1	PTF

29	17 Sep 1873	Liguria orientale	VI-VII	5.4	N/A	Y		---	#4	EL
35	17 Mar 1875	Romagna sud-orientale	VIII	5.9	N/A	N	The Composite and Individual sources responsible for this earthquake are described in KASTELIC <i>et al.</i> , 2013.	ITIS036; ITCS039	#1	N/A
5	7 Jun 1891	Valle d'Ilasi	IX	5.9	Y	N	Strong, damaging aftershocks reported on 11 Jun, 15 Jun, 29 Jun, 7 Aug, 21 Aug 1891.	---	-	-
17	4 Mar 1898	Valle del Parma	VII-VIII	5.4	N/A	N	---	ITCS046	#1	PTF
3	30 Oct 1901	Salò	VIII	5.7	N/A	N	---	ITIS069; ITCS048	#1	SAMF
16	13 Jan 1909	Bassa Padana	VI-VII	5.5	N/A	Y	From MELONI and MOLIN (1987). This earthquake falls near the ITCS012, but the ITCS012 is not responsible for it, because the 1909 event is deeper than the ITCS012. Epicentral area very close to that of the 1796 earthquake (ID15).	---	#4	PSL
36	17 May 1916	Alto Adriatico	VIII	5.9	Y	N	The Composite and Individual Sources responsible for this earthquake are described in KASTELIC <i>et al.</i> (2013).	ITIS034; ITCS030	#1	N/A
37	16 Aug 1916	Alto Adriatico	VIII	6.1	Y	N	The Composite and Individual Sources responsible for this earthquake are described in KASTELIC <i>et al.</i> (2013).	ITIS033; ITCS030	#1	N/A
19	20 Apr 1929	Bolognese	VII-VIII	5.3	Y	N	BOSCHI and GUIDOBONI (2003).	ITIS103; ITCS047	#1	PTF
8	15 May 1951	Lodigiano	VI-VII	5.4	N/A	Y	From MELONI <i>et al.</i> (1988). This earthquake falls near the ITCS044, but the ITCS044 is not responsible for it, because the 1951 event is deeper than the ITCS044.	---	#3	UDS
10	15 Jul 1971	Parmense	VIII	5.7	N/A	N	---	ITCS009	#1	EA

Table 2: Parameters of the largest historical earthquakes ($M \geq 5.3$) that occurred in the study region (from BOSCHI and GUIDOBONI, 2003, and ROVIDA *et al.*, 2011). Positively shallow and deep historical earthquakes are highlighted in light grey and dark grey, respectively (the background is white when depth is undefined). Each earthquake is tentatively assigned to a Group and when possible also to a Tectonic structure. Y: Yes; N: No; N/A: Not Applicable. See Figure 3 for earthquake locations. Earthquakes belonging to the same sequence are listed together. EA: Emilia Arc; FRA: Ferrara-Romagna Arc; PTF: Pedepenninic Thrust Front; SAMF: Southern Alps Mountain Front;

SAOA: Southern Alps Outer Arc; DR: Deep ramp; SVL: Schio-Vicenza Line; AVML: Arbia- Val Marecchia Line; PSL: Prato-Sillaro Line; VVL: Viareggio-Val di Lima-Bologna Line; EL: Enza Line; ML: Montone Line; UDS: Unknown Deep Structure.

Table 3: Parameters of the largest instrumental earthquakes ($M \geq 4.5$) in the study region (from ISIDe and *Bollettino Sismico Italiano*).

Earthquakes shallower and deeper than 15 km are highlighted in light grey and dark grey, respectively (see Figure 3 for earthquake locations). FM Ref: Source of focal mechanism: TDMT, <http://cnt.rm.ingv.it/tdmt.html> (from 24 Nov 2004); PON, PONDRELLI *et al.*, 2006.

*=Depth from CSI <http://csi.rm.ingv.it/> (CASTELLO *et al.*, 2006). Key to tectonic structures as in Table 2.

#	Date	Locality	M _w	Intensity	Kinematics	Multiple	Deep
1	1962, 21 August	Irpinia	6.1	IX	Normal	Y	N
2	1963, 19 July	Mar Ligure	6.0	VI	Thrust	Y	N
3	1968, 14 January	Valle del Belice	6.5	X	Thrust	Y	N
4	1976, 6 May	Friuli	6.4	IX-X	Thrust	Y	N
5	1978, 15 April	Golfo di Patti	6.0	VIII	Strike-slip	N	N
6	1979, 19 September	Valnerina	5.8	VIII-IX	Normal	N	N
7	1980, 23 November	Irpinia-Basilicata	6.7	X	Normal	Y	N
8	1984, 7 May	Appennino abruzzese	5.8	VIII	Normal	Y	N
9	1990, 5 May	Potentino	6.0	VII	Strike-slip	Y	Y
10	1997, 26 September	Appennino umbro-marchigiano	5.9	IX	Normal	Y	N
11	2002, 6 September	Palermo	5.8	VI	Thrust	N	N
12	2002, 31 October	Molise	5.8	VII-VIII	Strike-slip	Y	Y
13	2009, 6 April	L'Aquila	6.2	IX-X**	Normal	N	N
14	2012, 20 May	Emilia	5.9*	VIII***	Thrust	Y	N

Table 4: Summary of the 14 largest Italian earthquake sequences ($M_w \geq 5.7$) of the past 50 years (1962-2012: data from CPTI11). See Figure 4 for earthquake locations. Ten out of 14 of these sequences were multiple or complex events, i.e. they were characterized by at least two mainshocks whose magnitude is within 0.3 units of each other, and two were “deep crustal”. As each sequence included at least two - but also more - individual earthquakes above the given magnitude threshold, the total number of events considered is nearly 30. *M_L from ISIDE DATABASE (2012); ** TERTULLIANI *et al.* (2012a); *** TERTULLIANI *et al.* (2012b).

Depth	Historical (1117-1982) <i>dyne x cm</i>	Instrumental (1983-2012) <i>dyne x cm</i>	Grand total <i>dyne x cm</i>
Shallow earthquakes (<15 km)	2.93x10 ²⁶ (96% of total historical)	2.14x10 ²⁵ (84% of total instrumental)	3.14x10 ²⁶ (95% of grand total)
Deep earthquakes (>15 km)	1.24x10 ²⁵ (4% of total historical)	3.96x10 ²⁴ (16% of total instrumental)	1.64x10 ²⁵ (5% of grand total)
Total moment release	3.05x10 ²⁶ (92% of grand total)	2.54x10 ²⁵ (8% of grand total)	3.31x10 ²⁶ (100% of total)

Table 5: Summary of observed *historical* vs *instrumental* and *shallow* vs *deep* moment release in the Po Plain. The earthquakes for which the depth could not be evaluated (Table 2) have been considered shallow events. See text for discussion.
